Abstract

Numerous studies of the human brain have explored the relationship between cortical structures and brain development, cognitive function, and functional connectivity. Manual measurements of the cortical structures is extremely arduous, and often impractical, given the population sizes necessary for inferring statistical trends. Computational techniques have permitted large-scale studies, as they provide localized measurements characterizing the cortex with little or no human intervention. Useful to the neuroscience community are publicly available tools, such as the popular surface-based FreeSurfer, which facilitate the testing and refinement of hypotheses. Further motivating the adoption of such tools is the availability of robust parameter sets which have been tuned to provide good performance. For these reasons we developed the volume-based Advanced Normalization Tools (ANTs) cortical thickness automated pipeline comprising well-vetted components such as SyGN (multivariate template construction), SyN (image registration), N4 (bias correction), Atropos (*n*-tissue segmentation), and DiReCT (cortical thickness estimation). Although good repeatability is seen with both FreeSurfer and ANTs, such assessments of precision do not properly extend to inferences of accuracy or statistical modeling capabilities. For evaluation purposes, four open data sets (IXI, MMRR, NKI, and OASIS), consisting of approximately 1200 images, were processed by both the ANTs and FreeSurfer pipelines using standard processing protocols including the recently proposed “Desikan-Killiany-Tourville” (DKT) cortical labeling protocol. Measures of repeatability are augmented with straightforward demographic-based measures that illustrate strong predictive performance with ANTs over FreeSurfer. In addition to using open image data sets, to further promote open science, scientific reproducibility, and the use of the proposed ANTs pipeline, all scripts and results have been made publicly available.

Keywords: advanced normalization tools, age prediction, MRI, gender prediction, open science, scientific reproducibility

1. Introduction

Magnetic resonance imaging-based structural analysis of the human brain plays a fundamental role in identifying the relationship between cortical morphology, disease, and cognition. Discriminative cortical thickness values have been demonstrated in conditional abnormalities such as Huntington’s disease [74, 73, 78], schizophrenia [66], bipolar disorder [60], Alzheimer’s disease and frontotemporal dementia [23, 21], Parkinson’s disease [45], Williams syndrome [89], multiple sclerosis [71], autism [13, 39], migraines [18], chronic smoking [51], alcoholism [30], cocaine addiction [63], Tourette syndrome in children [87], scoliosis in female adolescents [93], early-onset blindness [42], chronic pancreatitis [33], obsessive-compulsive disorder [82], ADHD [1], obesity [70], and heritable [68] and elderly [8] depression. Evidence of cortical thickness variation has also been found to be a function of age [49], gender [57], untreated male-to-female transsexuality [58],

handedness [56, 2], intelligence [81], athletic ability [96], meditative practices [54], musical ability [9, 31], tendency toward criminality [69], childhood sexual abuse in adult females [41], and Tetris-playing ability in female adolescents [36]. Additionally, recent studies demonstrate correlated anatomical relationships using cortical thickness measures [99, 55, 40, 12]. Although these findings are subject to debate and interpretation [34], the availability of quantitative computational methods for extracting a measure of cortical thickness has proven invaluable for developing and refining fundamental neuroscience hypotheses.

Computational methods for analyzing the cortex may be broadly characterized as surface mesh-based or volumetric [76, 14]. Representative of the former is the FreeSurfer² cortical modeling software package [16, 28, 26, 27, 29] which owes its popularity to public availability, excellent documentation, good performance, and integration with other toolkits, such as the extensive FMRIB software library (FSL) [86]. Similar to other surface-based cortical thickness estimation approaches (e.g., [19, 62, 61, 46]), the outer cortical and gray/white matter surfaces from individual subject MR data are modeled with

²<http://surfer.nmr.mgh.harvard.edu/>

polygonal meshes which are then used to determine local cortical thickness values based on a specified correspondence between the surface models.

Image volumetric (or meshless) techniques vary both in their algorithms as well as in the their underlying definitions of cortical thickness. An early, foundational technique is the method of [43] in which the inner and outer surface geometry is used to determine the solution to Laplace's equation where thickness is measured by integrating along the tangents of the resulting field lines spanning the boundary surfaces. Subsequent contributions improved upon the original formulation. For example, in [101], a Eulerian partial differential equation approach was proposed to facilitate the computation of correspondence paths. Extending the surface-based work of [61], the hybrid approach of [46] uses the discrete Laplacian field to deform the white matter surface mesh towards the outer cortical surface. Although the Laplacian-based approach has several advantages including generally lower computation times and non-crossing correspondence paths, direct correlative assessments with histology are potentially problematic as the quantified distances are not necessarily Euclidean. Other volumetric algorithms employ coupled level sets [102], model-free intelligent search strategies either normal to the gray-white matter interface [76], or using a min-max rule [92]. Most relevant to this work is the DiReCT (Diffeomorphic Registration-based Cortical Thickness) algorithm proposed in [17] where generated diffeomorphic mappings between the gray/white matter and exterior cortical surfaces are used to propagate thickness values through the cortical gray matter. A unique benefit of DiReCT is that it naturally estimates the boundaries of buried sulci by employing a diffeomorphic constraint on the probabilistic estimate of the gray matter and cerebrospinal fluid interface.

Although a variety of techniques exist for estimating cortical thickness from imaging data (of which only a fraction are cited here), several common preprocessing components can be identified. The most fundamental of these include inhomogeneity correction, skull stripping, and *n*-tissue segmentation for differentiating gray and white matter. For statistical analysis across large populations, construction of population-specific unbiased templates is also potentially beneficial [25]. In addition, intermediate steps might include a crucial registration component (e.g., propagating template-based tissue priors for improved segmentation).

Cortical thickness studies are made more complex by the need for large neuroimaging data sets such as that provided by the Alzheimer's Disease Neuroimaging Initiative (ADNI) [97] and the increasing importance of translational research and the packaging of state-of-the-art research methods so that other researchers can more easily use them. Currently, the National Institutes of Health (NIH) mandates that any NIH-funded data resources, including MRI, must be released to the public. In contrast to ADNI, which provides standardized data acquisition protocols used across all sites, these smaller-scale projects are collected in an unstructured way. Therefore, neuroimage processing tools must reliably quantify even when there is a relative lack of quality control over the input data. While robustness is a goal shared by all software development targeted at

neuroscience research, very few methods have been thoroughly tested on large and unstructured neuroimaging data sets.

The general lack of availability of published algorithms [50] (not to mention critical preprocessing components) is a strong deterrent to the use or evaluation of these algorithms by external researchers. For example, one recent evaluation study [14] compared FreeSurfer (a surface-based method) with two volumetric methods [43, 17]. Whereas the entire FreeSurfer processing pipeline has been made publicly available, refined by the original authors and other contributors, and described in great detail (specifically in terms of suggested parameters), both volumetric methods were implemented and run by the authors of the evaluation (not by the algorithm developers) using unspecified parameters with relatively small, private data sets, making the comparisons less than ideal (see [91] for further discussion concerning the issue of instrumentation bias and scientific reproducibility in the use and evaluation of software). Further complicating such comparisons is the potential for bias, such as interpolation artifacts when converting surface to volume data or vice versa [47].

We provide below a brief description of our proposed pipeline, which produces a volumetric cortical thickness map from an individual subject's T1-weighted MRI. Additionally, we note that it is freely available as part of the Advanced Normalization Tools (ANTs) software package. This includes all the necessary preprocessing steps consisting of well-vetted, previously published algorithms for bias correction [90], brain extraction [4], *n*-tissue segmentation [6], template construction [7], and image normalization [5]. More importantly, we provide explicit coordination among these components within a set of well-documented shell scripts which are also available in the ANTs repository where parameters have been tuned by ANTs developers (N.T. and B.A.). A fully functional, self-contained example to be run on 2-dimensional image data is provided at the Github repository associated with this work.³

Here we demonstrate the use of the described framework in processing 1200 publicly available, T1-weighted brain MR images drawn from four well-known data sets. For comparative evaluation we also process the same data using the standard FreeSurfer cortical thickness processing protocol. Similar to previous work [e.g., 14], we are able to report repeatability assessments for both frameworks using subsets of the data with repeated acquisitions.

However, repeatability (or, more generally, *precision*) is not conceptually equivalent to *accuracy* and, thus, does not provide a complete perspective for determination of measurement quality. Although FreeSurfer validation has included histological [74] and image-drawn [52] comparisons, such manual assessments were extremely limited in terms of number of subjects and the number of cortical regions. In addition, there was no mention in these studies of the number of human observers making these measurements nor discussion of quality assurance. Therefore, given that ground-truth measurements are not available for these data, we use demographic-based predictive

³<http://www.github.com/ntustison/KapowskiChronicles/>

assessments to show that ANTs outperforms FreeSurfer-based thickness estimation for these data, based on well-studied relationships between cortical thickness and age/gender.

Finally, we make available all data from both ANTs and FreeSurfer processing outcomes. This includes derived image data, processing scripts, and tabulated results. The availability of both the code and data enables the set of results described in this work to be fully reproducible.

2. Methods and Materials

2.1. ANTs volume-based cortical thickness estimation pipeline

The ANTs cortical thickness estimation workflow is illustrated in Figure 1. The steps are as follows:

1. Initial N4 bias correction on input anatomical MRI
2. Brain extraction using a hybrid segmentation/template-based strategy
3. Alternation between prior-based segmentation and “pure tissue” posterior probability weighted bias correction
4. DiReCT-based cortical thickness estimation
5. Optional normalization to specified template and multi-atlas cortical parcellation

Each component, including both software and data, is briefly detailed below with the relevant references for additional information.

The coordination of all the algorithmic components is encapsulated in the shell script `antsCorticalThickness.sh` with subcomponents delegated to `antsBrainExtraction.sh` and `antsAtroposN4.sh`. A representative script command is reproduced in Listing 1 for a single IXI subject to demonstrate the simplicity and mature status of what we propose in this work and a comparison with the analogous FreeSurfer command. Option descriptions are provided by invoking the help option, i.e., “`antsCorticalThickness.sh -h`”.

Listing 1: Analogous ANTs and FreeSurfer command line calls for a single IXI subject in the evaluation study.

2.1.1. Anatomical template construction

Registering (“normalizing”) images to a standard coordinate system reduces intersubject variability in population studies. Various approaches exist for determining the normalization or

coordinate space, such as the selection of a pre-existing template based on a single individual (e.g., the Talairach atlas [88]) or a publicly available average of multiple individuals (e.g., the MNI [15] or ICBM [64] templates), or an average template constructed from the individuals under study. The work of [7] explicitly models the geometric component of the normalized space during optimization to produce such mean templates. Coupling the intrinsic symmetry of SyN pairwise registration [5] and an optimized shape-based sharpening/averaging of the template appearance, Symmetric Group Normalization (SyGN) is a powerful framework for producing optimal population-specific templates.

The ANTs implementation of this technique is currently available as a shell script, `buildtemplateparallel.sh`. A generalized, multivariate version is also available as `antsMultivariateTemplateConstruction.sh`. Both scripts are distributed as part of the ANTs software. The multivariate script permits the construction of multimodal templates (e.g., T1-weighted, T2-weighted, proton density MRI and fractional anisotropy). Both scripts accommodate a variety of computational resources for facilitating template construction. These computational resource possibilities include:

- serial processing on a single workstation
- parallelized processing on a single workstation with multiple cores using pexec⁴
- parallelized processing using Apple’s XGrid technology⁵
- parallelized processing using Sun Grid Engine for cluster-based systems⁶
- parallelized processing using the Portable Batch System for cluster-based systems⁷

For this work, database-specific templates were used during cortical thickness pipeline processing for both brain extraction and brain segmentation steps. We used multivariate templates because they had already been constructed for a previous study from the multimodal data sets, not because they have been demonstrated to confer an advantage over univariate templates (i.e., T1-only) for the proposed workflow.

2.1.2. N4 bias field correction

Critical to quantitative processing of MRI is the minimization of field inhomogeneity effects which produce artificial low frequency intensity variation across the image. Large-scale studies, such as ADNI, employ perhaps the most widely used bias correction algorithm, N3 [84], as part of their standard protocol [10].

In [90] we introduced an improvement of N3, denoted as “N4”, which demonstrates a significant increase in performance

and convergence behavior on a variety of data. This improvement is a result of an enhanced fitting routine (which includes multi-resolution capabilities) and a modified optimization formulation. For our workflow, the additional possibility of specifying a weighted mask in N4 permits the use of a “pure tissue” probability map (described below) calculated during the segmentation pipeline for further improvement of bias field estimation.

N4 is used in two places during the individual subject processing (cf Figure 1). It is used to generate an initial bias-corrected image for use in brain extraction. The input mask is created by adaptively thresholding the background from the foreground using Otsu’s algorithm [67]. Following brain extraction, six-tissue (cerebrospinal fluid, cortical gray matter, white matter, deep gray matter, brain stem, and cerebellum) segmentation involves iterating between bias field correction using the current pure tissue probability map as a weight mask and then using that bias-corrected image as input for the Atropos segmentation step (described below).

2.1.3. Brain extraction

Brain extraction using ANTs combines template building, high-performance brain image registration, and Atropos segmentation with topological refinements. An optimal template [7], i.e., a mean shape and intensity image representation of a particular cohort, is first constructed using structural MRI data that is accompanied by corresponding anatomical labels (e.g., the LPBA40 data set [79]). Template construction iterates between estimating the optimal template and registering each subject to the optimal template. Thus, the construction produces the transforms necessary to warp each subject’s la-

bels to the template space. We use these transformed labels to create a probabilistic estimate of the brain mask for the template. In this work, we perform the additional step of building separate templates for each cohort and propagating the probabilistic mask to each cohort template using registration of the T1-weighted templates (cf Figure 3). Further refinements include thresholding the warped brain probability map at 0.5 and dilating the resulting mask with a radius of two. Atropos is used to generate an initial three-tissue segmentation estimate within the mask region. Each of the three tissue labels undergoes separate morphological operations including hole-filling and erosion. These results are then combined to create the brain extraction mask which is further refined by additional dilation, erosion, and hole-filling operations. The complete workflow is found in the script `antsBrainExtraction.sh`.

In an evaluation study, we compared an earlier version of our extraction method with publicly available brain extraction algorithms, including AFNI’s 3dIntracranial [95], FSL’s BET2 [85], FreeSurfer’s `mri_watershed` [77], and BrainSuite [22]. We demonstrated that our combined registration/segmentation approach [4] performed with an accuracy comparable to FreeSurfer and a parameter-tuned version of BrainSuite. Figure 2 presents a visual comparison of results derived with the current ANTs brain extraction method and results obtained using FreeSurfer.

2.1.4. Atropos six-tissue segmentation

In [6] we presented an open source *n*-tissue segmentation software tool (which we denote as “Atropos”) that attempts to distill over 20 years of active research in this area, in particular some of the most seminal work (e.g., [103, 3]). Specifi-

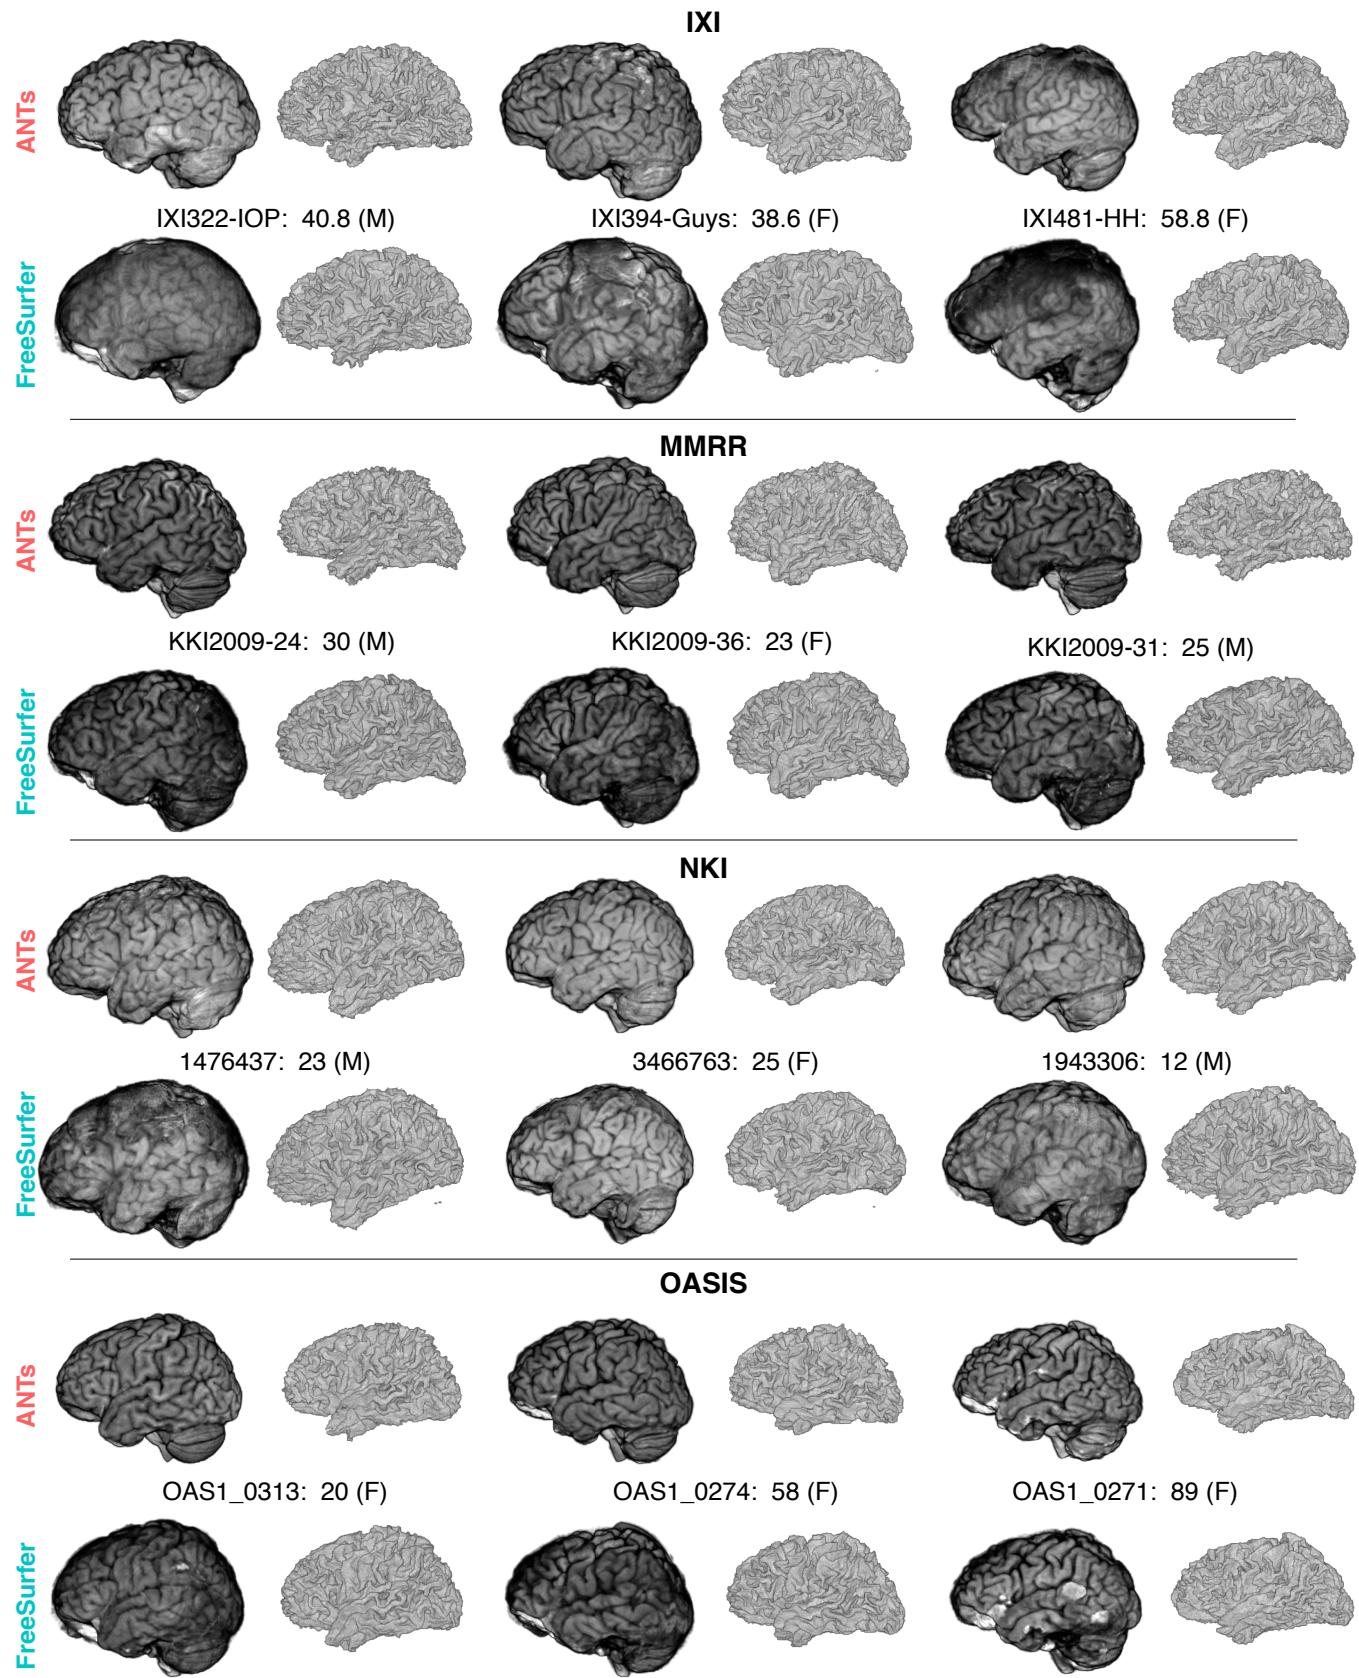

Figure 2: Representative sample of volume brain renderings from the four different cohorts (IXI = rows 1 and 2, MMRR = rows 3 and 4, NKI = rows 5 and 6, OASIS = rows 7 and 8), illustrating the qualitative difference between ANTs and FreeSurfer results, which are arranged top-and-bottom for each subject. Each brain was rigidly registered to the OASIS template for rendering purposes. With each subject we provide subject ID, age, and gender.

cation of prior probabilities includes spatially varying Markov Random Field modeling, prior label maps, and prior probability maps typically derived from our template building process. Additional capabilities include handling of multivariate data, partial volume modeling [80], a memory-minimization mode, label propagation, a plug-and-play architecture for incorporation of novel likelihood models which includes both parametric and non-parametric models for both scalar and tensorial images, and alternative posterior formulations for different segmentation tasks.

Due to the important interplay between segmentation and bias correction, we perform multiple N4 \rightleftharpoons Atropos iterations. In order to better integrate Atropos and N4, we use a pure tissue probability weight mask generated from the posterior probabilities derived from the segmentation step. Given N labels and the corresponding N posterior probability maps $\{P_1, \dots, P_N\}$ produced during segmentation, the N4 weight mask is created at each N4 \rightleftharpoons Atropos iteration from

$$P_{pure\ tissue}(\mathbf{x}) = \sum_{i=1}^N P_i(\mathbf{x}) \prod_{j=1, j \neq i}^N (1 - P_j(\mathbf{x})). \quad (1)$$

One of the key insights of the original N3 development is the observation that inhomogeneities cause the intensity values of pure tissue peaks to spread in the intensity histogram as though convolved with a Gaussian. A core contribution of N3 is the proposed corrective step of deconvolving the intensity histogram to accentuate the tissue peaks, coupled with a spatial smoothing constraint. The pure tissue probability mask weights more heavily the voxels corresponding to pure tissue types (as determined by the segmentation) during the deconvolution process while minimizing the contribution of regions such as the gray/white matter interface where peak membership is ambiguous.

Atropos enables prior knowledge to guide the segmentation process where template-based priors are integrated into the optimization with a user-controlled weight. Modulating the likelihood and prior contributions to the posterior probability is essential for producing adequate segmentations. Atropos weights the likelihood and priors according to $P(x|y) \propto P(y|x)^{1-\alpha} P(x)^\alpha$ where α is a user-selected parameter which weights the tradeoff between the likelihood and priors terms. In this work, we chose a weighting of $\alpha = 0.25$ based on our extensive experimentation with different parameter weights.

Since cortical thickness estimation only requires the cortical gray and white matter, the deep gray and white matter (both labels and posterior maps) are combined to form a single “white matter” set. This white matter set and the cortical gray matter are the only results from the segmentation step that are used by the DiReCT algorithm (described below).

2.1.5. DiReCT cortical thickness estimation

DiReCT was introduced in [17] and was made available in ANTs as the program *KellySlater*. Since then several improvements have been made and incorporated into the program

Table 1: The 31 cortical labels (per hemisphere) of the DKT atlas.

KellyKapowski.⁸ The more recent implementation has made numerous advances, including: it is multi-threaded, written in rigorous ITK coding style,⁹ and has been made publicly available through ANTs, complete with a unique command line interface design developed specifically for ANTs tools.

2.2. Public data resources

The above pipeline was run on four publicly available data sets: IXI, MMRR, NKI, and OASIS. In addition, we used a subset of the MindBoggle-101 data¹⁰ labeled using the Desikan-Killiany-Tourville (DKT) protocol [48] to define the regions of interest (ROI). All five data sets are described below.

2.2.1. MindBoggle-101 data for ROI definitions

In [48] the authors proposed the DKT cortical labeling protocol—a modification of the popular Desikan-Killiany protocol [20] to improve cortical labeling consistency and to improve FreeSurfer’s cortical classification of 31 cortical regions per hemisphere, listed in Table 1. For the latter, forty manually labeled brains were used to construct the DKT40 Gaussian classifier atlas, which is now bundled with current versions of FreeSurfer and used to automate anatomical labeling of MRI data. Since the regional thickness values generated by FreeSurfer follow this protocol, these anatomical labels provide a common standard for comparison between ANTs and FreeSurfer.

The work of [48] also resulted in a publicly available set of manually edited labels following the DKT protocol in 101 T1-weighted brain images from different sources, including a

⁸Traditional academic discourse encountered in the published literature rarely contextualizes peculiarities such as algorithmic nomenclature. We briefly mention that this was the source of a rare disagreement between the first and last authors based, as many disagreements are, on a simple misunderstanding and not an affronting existential statement concerning a certain favorite sitcom of the first author’s youth.

⁹<http://www.itk.org/ITK/help/documentation.html>

¹⁰<http://mindboggle.info/data.html>

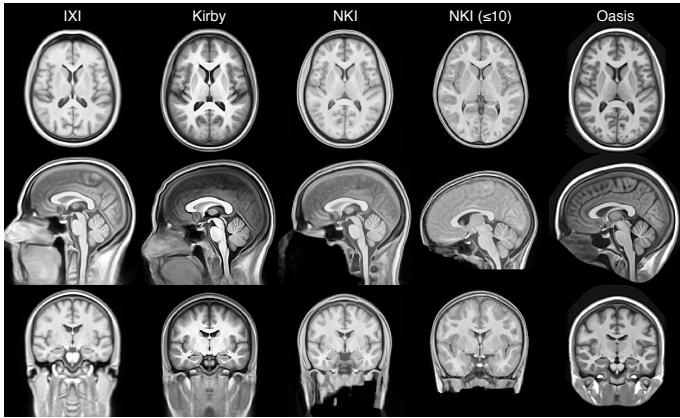

Figure 3: Population-specific templates for each of the four public data sets used for cortical thickness estimation. These templates were generated using the script `antsMultivariateTemplateConstruction.sh`. The benefit of using such population-specific templates is obvious when one sees the variability in acquisition and data preparation (e.g., defacing protocols).

subset of 20 images from the OASIS data set (specifically, the test-retest data). These 20 images are used in the ANTs multi-atlas label propagation [94] step that defines the volumetric regions for each subject. This was performed using the program `jointfusion` with default parameters which is also distributed with the ANTs toolkit and simplified with the `antsMultiLabeling.sh` script. Cortical thickness values are averaged within each labeled region for each subject using only the non-zero voxels from the cortical thickness map.

2.2.2. Public data for thickness estimation evaluation

We applied the same pipeline to diverse publicly available data sets collected from multiple sites and with a mixture of 3T and 1.5T T1-weighted brain images. Subjects in this data set span the age range from 4 to 96 years old. This strategy tested robustness to variation in head position, brain shape, defacing, image contrast, inhomogeneity, imaging artifacts, and the broad variation in extracerebral tissue. Failure can occur in initial brain extraction, segmentation, registration, or bias correction, any of which can lead to an inaccurate cortical thickness measurement.

In total, we processed 1,205 T1-weighted images from four different public data sets to obtain cortical thickness maps. Below we describe the four data sets:

IXI. Initially, we processed 581 T1-weighted images from the IXI¹¹ data set, but only 563 subjects (313 females, 250 males) were included in the post processing analysis due to missing demographic information, which would have prevented an accurate estimate of the age at the time of image acquisition. These data were imaged at three sites with several modalities acquired (T1-weighted, T2-weighted, proton density, magnetic resonance angiography, and diffusion tensor imaging). The database also includes demographic information such as date of birth, date of scan, weight, height, ethnicity, occupation category, educational level, and marital status.

¹¹<http://biomedic.doc.ic.ac.uk/brain-development/>

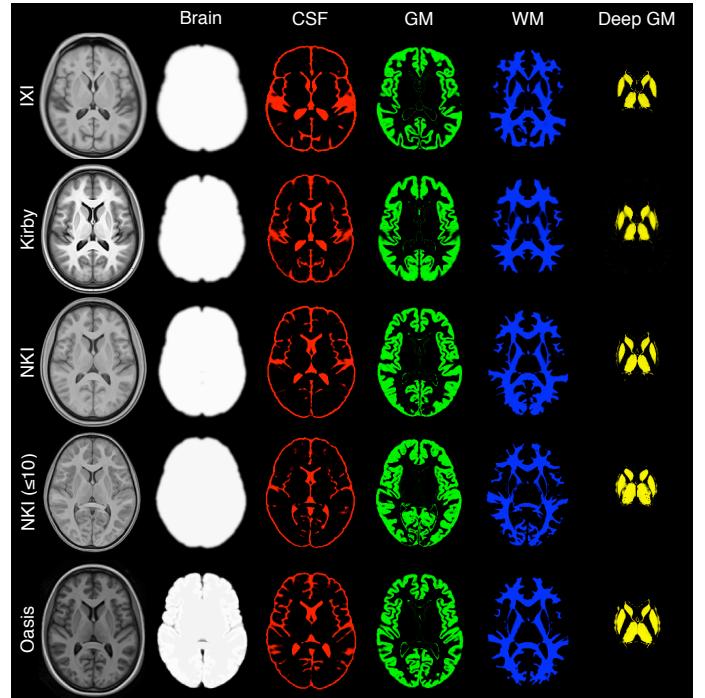

Figure 4: Axial slices from each of the five T1 templates including the corresponding probability masks used for brain extraction and brain tissue segmentation. Not shown are the prior probability maps for brain stem and cerebellum regions.

MMRR. The Multi-Modal MRI Reproducibility Resource (MMRR)¹² data set, was originally described in [53] consisting of 21 subjects (10 females, 11 males) and features a rich set of modalities, as well as repeated scans.

NKI. In support of open science, the 1,000 Functional Connectomes Project¹³ was initiated on December 11, 2009 by various members of the MRI community seeking to form collaborative partnerships among imaging institutions for sharing well-documented multimodal image sets accompanied by phenotypic data. One such contribution is the Nathan Klein Institute (NKI)/Rockland sample, consisting of 186 T1-weighted images (87 females, 99 males).¹⁴

OASIS. The initial Open Access Series of Imaging Studies (OASIS)¹⁵ data set consisted of 433 T1-weighted images. We processed all of these, but 100 were excluded from our analysis due to probable Alzheimer’s disease ($CDR > 0$) and an additional 20 repeat scans were excluded, resulting in 313 individual subject scans included in the normal group statistical analysis (118 males, 195 females). Ages were between 18 and 96 and all subjects are right-handed.

2.3. Processing miscellany

Given the documented variability in FreeSurfer results with version and operating system [35] (as we would expect with

¹²<http://www.nitrc.org/projects/multimodal/>

¹³http://fcon_1000.projects.nitrc.org

¹⁴Downloaded on September 22, 2012.

¹⁵<http://www.OASIS-brains.org/>

our own ANTs pipeline), all data was processed using the same ANTs and FreeSurfer versions on the same hardware platform. Processing was performed using the Linux (CentOS release 6.4) cluster at the University of Virginia¹⁶ using single-threading with a maximal requested memory footprint of 8 gb for ANTs and 4 gb for FreeSurfer. The development version of ANTs was used for processing (git commit tag: 69d3a5a6c7125ccf07a9e9cf6ef29f0b91e9514f, date Dec. 11, 2013). FreeSurfer version 5.3 x86_64 for CentOS was downloaded on 5 December, 2013 (“freesurfer-Linux-centos6_x86_64-stable-pub-v5.3.0”, release date: 15 May, 2013).

3. Evaluation

Traditional assessment approaches, such as manual labeling, are inadequate for evaluating large-scale performance. We therefore sought to minimize failure rate, quantify the repeatability of cortical thickness measures, and determine whether the ANTs pipeline reveals biologically plausible relationships between the cortex, gender,¹⁷ and age and how its performance compares to the current de facto standard of FreeSurfer-derived thickness estimation. Collectively, these surrogate measurements allow us to establish data-derived relative performance standards. Additionally, for completeness, we include timing results as that factors into usability.

3.1. Repeatability

Repeat scans of 40 subjects (20 MMRR subjects and 20 OASIS subjects) were used to determine the repeatability of regional cortical thickness measurements, T . Similar to the reproducibility assessment given in [44], we demonstrate this in terms of the percent variability error:

$$\varepsilon = \frac{|T_{\text{scan}} - T_{\text{rescan}}|}{0.5 \times (T_{\text{scan}} + T_{\text{rescan}})}. \quad (2)$$

Comparison of the ANTs and FreeSurfer percent variability errors for the 62 DKT regions for both the OASIS and MMRR scan-rescan data sets are given in Figure 5. Although the variance is slightly greater for the set of ANTs measurements, statistical testing per cortical region (two-tailed paired t-test, corrected using false discovery rate) did not indicate non-zero mean differences for either approach for any region.

We also calculated the intraclass correlation coefficient (“ICC(2,1)” in the notation of [83]) to assess scan/rescan reliability. The ANTs thickness pipeline produced an ICC value of 0.98 and the FreeSurfer thickness pipeline yielded an ICC value of 0.97, indicating good scan/rescan reliability for both ANTs and FreeSurfer.

3.2. Age prediction assessment

Despite good repeatability with both ANTs and FreeSurfer, such measures do not provide an assessment of accuracy or even relative utility. For example, strong priors can yield good repeatability measures but potentially at the expense of data fidelity thus compromising the quality of models (statistical or otherwise) built from such results. Given that ground truth is not available for these data nor for the many studies looking at brain morphology, an indirect method (or set of methods) is required for determining the quality of thickness estimation.

Previous research has used predictive modeling for comparing cortical thickness algorithms. For example, in [14], classification of healthy, semantic dementia, and progressive non-fluent aphasia categories using regional cortical thickness values was used to determine the predictive modeling capabilities of different cortical thickness processing protocols in 101 subjects. However, differential diagnosis of dementia [65] is not as straightforward as obtaining a subject’s age or gender and regressing that against cortical thickness; the latter constitute biological relationships that have been well-studied and reported in the literature.

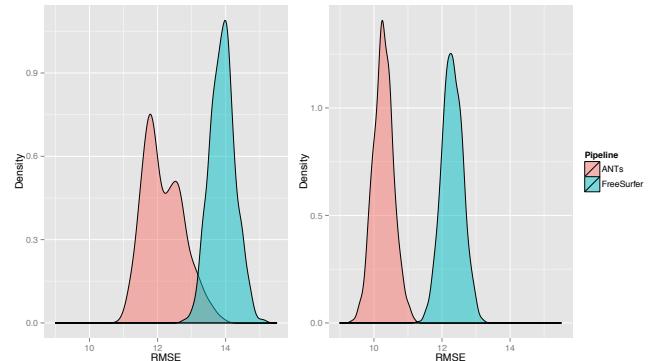

Figure 6: Age prediction RMSE distributions of linear (left) and random forest (right) models for the ANTs- and FreeSurfer-derived thickness values. For both prediction models ANTs RMSE error is lower.

For our first assessment, we modeled age versus regional cortical thickness values to determine which framework produces better predictive thickness estimates. We first subdivided the thickness data into training and testing subsets with an even split between the two subsets.¹⁸ We then used the training data to create two models for each pipeline: 1) standard linear regression and 2) random forests (a non-parametric machine learning technique) [11], for estimating age from both ANTs and FreeSurfer thickness values in the testing data.

The formula (in the notation of [98]) for the linear model is

$$AGE \sim VOLUME + \sum_{i=1}^{62} T(DKT_i) * GENDER \quad (3)$$

¹⁶<http://www.uvacse.virginia.edu/>

¹⁷We recognize the distinction often made between “sex” and “gender” (<http://www.who.int/gender/whatisgender/en/>). As the demographic information collected during the course of the imaging studies is presumably self-reported, we assume that most self-identify in terms of gender and, therefore, use the term “gender” in data descriptions.

¹⁸We tried various training proportions between 10 and 90% (in increments of 10%) to see if that had an effect on relative performance for both age and gender prediction comparisons. Although age predictive capabilities for both pipelines showed improvement (gender prediction was mostly unaffected), the relative outcomes were the same.

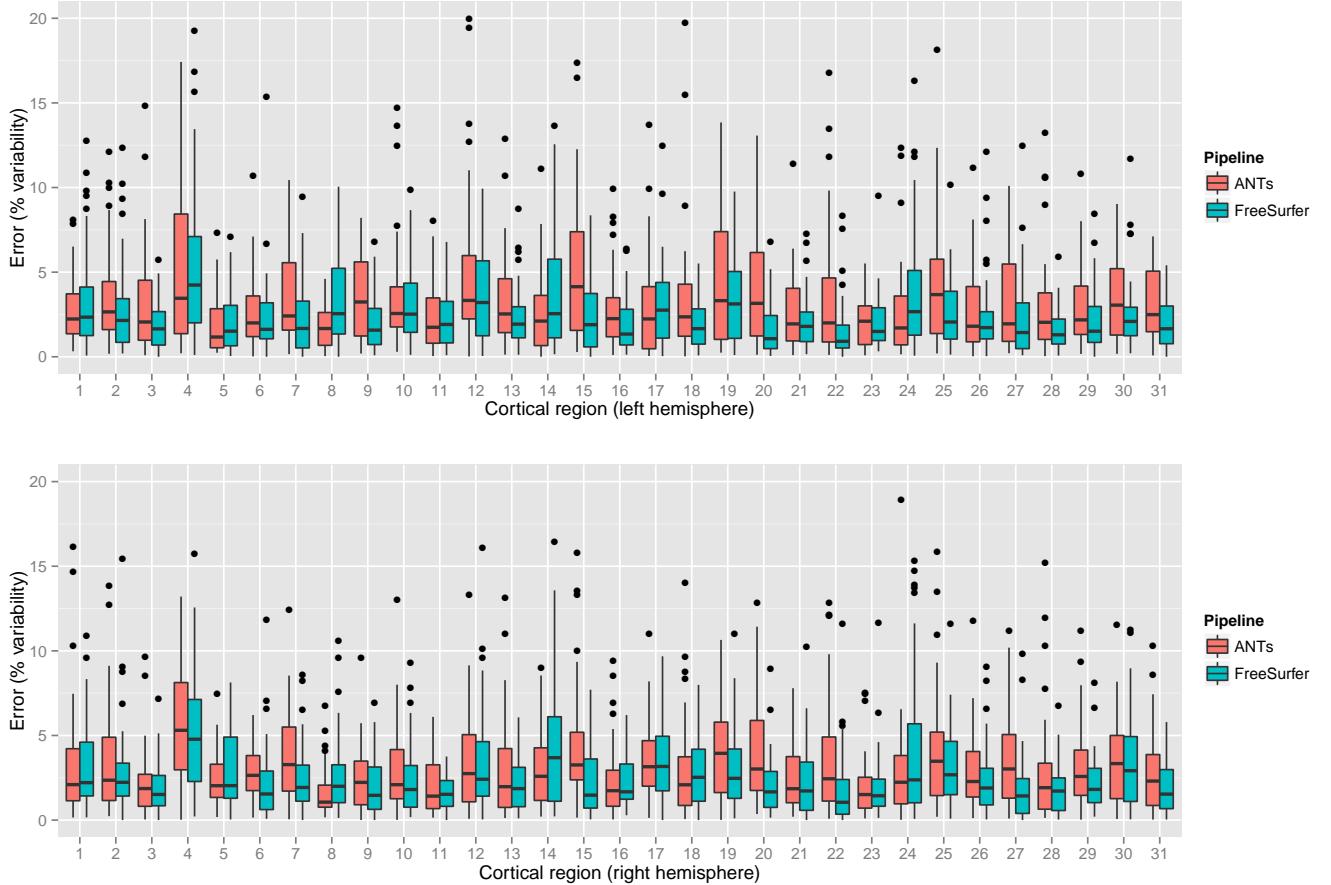

Figure 5: Percent error variability for both ANTs and FreeSurfer pipelines over the left and right hemispheres of both the MMRR and OASIS data subsets within the 62 regions defined by the Desikan-Killiany-Tourville atlas. Both methods demonstrate good repeatability qualities.

where $T(DKT_i)$ is the average thickness value in region DKT_i . Similarly, the random forest model was specified as a combination of all terms using the `randomForest`¹⁹ package in R with the default settings and 200 trees.

In order to ensure a fair comparison, the procedure described above consisting of training and testing steps was performed for $n = 1000$ permutations to elicit a performance distribution which we measure using the relative mean square error (RMSE):

$$RMSE = \sqrt{\frac{\sum (AGE_{true} - AGE_{predicted})^2}{N}}. \quad (4)$$

The resulting distributions are illustrated in Figure 6 with the linear model results displayed on the left and random forest results on the right. The RMSE value was lower with ANTs thickness values for both models with the ANTs-based random forest predictions performing the best. Mean RMSE values are provided in Table 2.

Table 2: Mean RMSE for age prediction (in years).

	Linear	Random Forest
ANTs	12.2	10.3
FreeSurfer	13.9	12.3

3.3. Gender prediction assessment

We also performed a similar prediction assessment using gender as the regressand. The binomial generalized linear model is

$$GENDER \sim VOLUME + \sum_{i=1}^{62} T(DKT_i) * AGE \quad (5)$$

where $T(DKT_i)$ is the average thickness value in region DKT_i . We then characterized performance using a ROC curve for both methods (see Figure 7) where we averaged over 1000 permutations. The mean area under the curve (AUC) for both methods was also quantified with values of $ANTs_{AUC} = 0.83$ and $FreeSurfer_{AUC} = 0.78$.

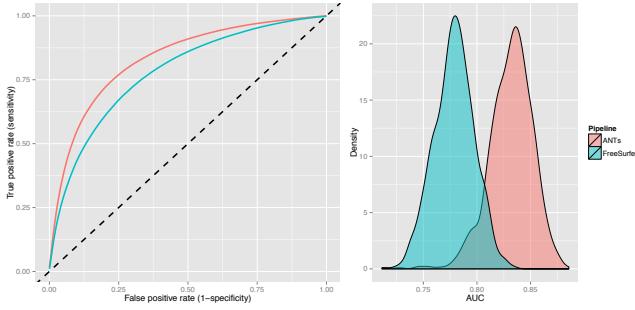

Figure 7: Average ROC curve and corresponding AUC distributions for gender prediction using ANTs and FreeSurfer thickness values. Values were averaged for 1000 permutations resulting in mean values of $\text{ANTs}_{\text{AUC}} = 0.83$ and $\text{FreeSurfer}_{\text{AUC}} = 0.78$.

3.4. Computation time

All images underwent the ANTs and FreeSurfer pipeline processing using the computational cluster at the University of Virginia. Processing times varied approximately between 10–20 hours per subject for both pipelines for the entire cortical thickness estimation procedure although ANTs processing, on average, took slightly longer (cf Figure 8). Averaged over all cohorts, ANTs required 15.7 ± 2.0 hours per subject and FreeSurfer required 14.1 ± 2.9 hours per subject.

The propagation of the DKT labels to each subject using label fusion as described earlier was performed in parallel and took anywhere between 40 and 80 hours per subject for 16 serial image registrations and application of the joint label fusion algorithm [94]. Note that the script mentioned earlier `antsMafLabeling.sh` parallelizes the registration component which decreases the time for parallel computation platforms.

4. Discussion

In the absence of ground truth, we used repeatability and prediction of demographic variables to compare the ANTs and FreeSurfer cortical thickness pipelines. One very important issue that was not discussed in this work is quality control for ensuring proper pipeline processing. The time required to go through approximately 1200 sets of results ($\times 2$ for both pipelines) would be enormous (not to mention the tedium). However, the first author did do this for the brain extraction step to ensure that both pipelines were achieving expected intermediate results. The only major failure was the FreeSurfer brain extraction of a single IXI subject (IXI430-IOP-0990). Also, three NKI subjects were not processed to completion with FreeSurfer (1713515, 18755434, and 2674565) and were not included in the analysis. Although researchers might quibble over processing minutiae such as the inclusion of too much (or not enough) of the meninges, we approached our evaluation using more objective criteria which concern all those engaged in

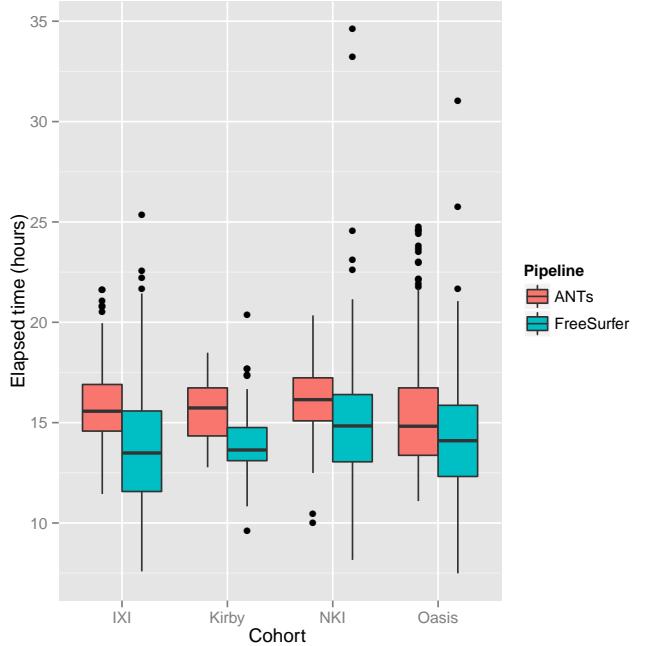

Figure 8: Elapsed time across data sets for ANTs and FreeSurfer processing. Averaged over all cohorts, ANTs required 15.7 ± 2.0 hours per subject and FreeSurfer required 14.1 ± 2.9 hours per subject.

this type of research. We are currently trying to develop methods to facilitate data inspection for quick quality assurance/control.

4.1. Repeatability of thickness measurements

The OASIS data set and the MMRR data set allow us to test whether the same thickness values emerge from T1-weighted MRI collected on the same subject but at different times of the day or over a time separation within a few weeks. Although the ANTs cortical thickness pipeline produced similar repeatability assessments as FreeSurfer in these data, there are many additional issues to explore with the ANTs-based framework. Pre-analysis confounds such as short-term alterations in cortical morphology due to the T1-weighted susceptibility to blood flow [32, 75, 100] and MRI acquisition parameters such as field strength, site, resolution, scanner, longitudinal variation in scanner conditions, and pulse sequence [38, 59, 44] have been evaluated with FreeSurfer which has shown good reliability under various permutations of these conditions. Although we did not explicitly investigate the repeatability performance of the ANTs framework under such effects, the relatively good performance on the large and varied data (in terms of site, field strength, scanner, and acquisition sequence) used in this study provides confidence in its robustness to a variety of imaging conditions.

However, as we mentioned previously, good repeatability does not necessarily translate to accurate measurements. A crucial component in estimating cortical thickness is accurate gray matter segmentation for which several algorithms are available. A recent study compared FreeSurfer, FSL’s FAST [103], SPM8

¹⁹<http://cran.r-project.org/package=randomForest>

[3], and VBM8 (an extension of SPM8)²⁰ in terms of both reliability and accuracy [24]. Good accuracy was achieved with the latter three methods with Dice coefficients of > 0.93 for all regions in both simulated and real T1-weighted data. In contrast, FreeSurfer yielded slightly less accurate results (mean Dice > 0.88) on simulated data and even less accurate results for real data (mean Dice > 0.58). Despite the relatively poor accuracy, FreeSurfer was extremely reliable demonstrating the least variability in calculated gray matter volumes for single-subject, 10 scan data and the lowest average volume differences in the OASIS scan-rescan data.

4.2. Age and gender prediction

Although repeatability between ANTs and FreeSurfer is comparable, such measures are not as useful in determining the utility of the measuring software. That is the reason we used a training and testing paradigm to evaluate how well both frameworks produce measurements capable of predicting demographics which are well-known to correlate with cortical thickness. Additionally, these demographic measures are probably some of the easiest and most reliably obtained of all possible demographic measures used for this type of assessment. For age prediction, we used both a linear model (due to its general ubiquity) and a random forest model (a non-parametric model to contrast with the linear approach) which showed overall good performance. Also, the linear and random forest models have the advantage of being interpretable. That is, the models reveal the specific predictors that are most valuable which will be explored in future work. Another interesting result from the age prediction study was that predictive performance degenerated towards the 10% level, i.e. when using approximately 10% of the total number of subjects for training and the remaining 90% to test model predictive performance. This translates into approximately 100 subjects being used for training, raising concerns about the use of smaller cohorts for performance comparisons.

This study was limited to a cross-sectional investigation thus limiting extrapolations of ANTs performance to longitudinal data unlike recent FreeSurfer extensions which accommodate longitudinal data [72, 44]. Also, some users may choose to segment and register with ANTs and subsequently employ any alternative (e.g., surface-based) method for thickness estimation. Further work is needed by independent authors working on established pipelines to better compare surface-based and volume-based thickness reliability and accuracy across different populations, age ranges, and with longitudinal protocols.

4.3. Computation time

Computation time for the registration and segmentation components of the ANTs pipeline are substantial. It is likely that nearly as reliable results can be obtained in much less time for many of the subjects in this study. However, our interest in maximizing reliability and quality led us to employ parameters in the registration, segmentation, and bias correction that are

as robust as possible to differences in head position, the presence of large deformations between template and target brains and substantial inhomogeneity or other artifacts in the image content itself. Several subjects (e.g., NKI: 1898228, 1875434) provide examples of more difficult data from which we are able to extract meaningful segmentations and registrations, despite the presence of a “garbage-in/garbage-out” problem. A subject of future study is determining an exact cut-off for the inclusion of such data. We do not investigate this issue here, which has concerned statisticians for over half a century [37].

5. Conclusions

Imaging biomarkers such as cortical thickness play an important role in neuroscience research. Extremely useful to researchers are robust software tools for generating such biomarkers. In this work we detailed our open source offering for estimating cortical thickness directly from T1 images and demonstrated its utility on a large collection of public brain data from multiple databases acquired at multiple sites. To our knowledge, this study constitutes the largest collection of cortical thickness data processed in a single study. We anticipate that public availability of our tools and extensive tuning on the specified cohorts will prove useful to the larger research community. In this work, we only explored a portion of the potentially interesting investigations possible with these data. Since all of the data are publicly available, further work can be easily pursued by us or by other interested groups.
